Abstract | The large stomach worm, *Haemonchus*, commonly known as the barber’s pole worm, is a blood sucking nematode found in the abomasum of small and large ruminants. Allele-specific amplification of the rDNA internal transcribed spacer-2 (ITS-2) sequences was performed from the total of 78 individual adult worms to screen *Haemonchus placei* at species level, which is the significant diagnostic tool to identify this major economically important species. Further full sequences analysis of the ITS-2 region revealed that there are 4 sites shows intraspecific variations at position 65, 111, 125 and 148. For instance this study is the first documented report of intraspecific genetic variations in the rDNA ITS-2 sequences of *H. placei* from cattle in Pakistan and the results shows that *H. placei* is genetically different from the isolates studied previously. However, detailed and large size samples strategy will be required to identify the co-infection and interspecies hybridization between *H. placei* and *Haemonchus contortus* in cattle.

Keywords | *Haemonchus placei*, rDNA ITS-2, Pakistan

Gastrointestinal parasitic (GI) nematodes are extremely important agents of both human and animal disease (Sutherland and Leathwick, 2011). GI nematode infections constitute a significant threat to the health and welfare of grazing livestock throughout the world and impose a significant cost in terms of productivity in grazing animals. GI parasitic infections of livestock are among the most economically important diseases in the livestock of Pakistan (Annonymous, 2012–2013). The major GI nematode species in cattle are *H. placei*, *Ostertagia ostertagi*, *Mecistocirrus digitatus* and *Trichostrongylus axei*, *Strongyloides papillosus*, *Cooperia* and *Nematodirus* and *Oesophagostomum radiatum* found in the abomasum, small intestine and large intestine (Oku et al., 1987; Fukumoto et al., 1990). Of these species, *H. placei*, *O. ostertagi* and *Cooperia oncophora* are considered the most prevalent in cattle; in particular, the infection rate of *H. placei* was high. This nematode is commonly described as a large stomach worm, *Haemonchus*, commonly known as the barber’s pole worm, is a blood sucking nematode found in the abomasum of small and large ruminants. Allele-specific amplification of the rDNA internal transcribed spacer-2 (ITS-2) sequences was performed from the total of 78 individual adult worms to screen *Haemonchus placei* at species level, which is the significant diagnostic tool to identify this major economically important species. Further full sequences analysis of the ITS-2 region revealed that there are 4 sites shows intraspecific variations at position 65, 111, 125 and 148. For instance this study is the first documented report of intraspecific genetic variations in the rDNA ITS-2 sequences of *H. placei* from cattle in Pakistan and the results shows that *H. placei* is genetically different from the isolates studied previously. However, detailed and large size samples strategy will be required to identify the co-infection and interspecies hybridization between *H. placei* and *Haemonchus contortus* in cattle.
worn, namely, a trichostrongyloid nematode, and is an important blood-sucking nematode present in the abomasum of cattle. This parasite may cause mucosal inflammation, haemorrhage, ulcers and necrosis in the abomasum (Gennari et al., 1991). It appears to be confined mainly to Asian countries; however, it has also been found in North America, Australia, and Brazil. The movement of its hosts for agricultural purposes has resulted in the global spread of this parasite.

Generally, ruminants are concurrently infected with more than one species of GI nematodes, each having a different pathogenic effect on the host. It has been a difficult task to eradicate GI nematodes from grazing ruminants due to the variation in host susceptibility to the parasite, the wide distribution of nematodes in nature and the presence of wild ruminants. An effective method is required for the control of nematodes by reducing their infection rate and their transmission to the host in order to protect cattle for production losses. Strategies for the control of nematodes by using anthelmintic drugs should be devised based on the quantitation and identification of species (Mochizuki et al., 2006).

The rDNA ITS-2 region was amplified from individual Haemonchus adult worm lysates using a allele-specific forward primer complementary to 5’ prim end of rDNA ITS-2 coding sequence (HpITS-2F: 5’-ATACTACAATGTGGCTAG-3’) and reverse primer complimentary to the 3’ prim end of rDNA coding sequence (HpITS-2R: 5’-TGATAAAAA-GAACATCGT-3’). A 231bp fragment spanning the entire ITS-2 rDNA region was PCR amplified using a 50µl master mix containing final concentrations of 1X thermopol reaction buffer, 2mM MgSO4, 100µM of each dNTPs, 0.1µM forward and reverse primers and 1.25U Taq DNA polymerase (New England Biolabs). Thermo-cycling parameters were 95°C for 5 min followed by 35 cycles of 95°C for 1 min, 55°C for 1 min and 72°C for 1 min with a single final extension cycle of 72°C for 5 min.

The entire rDNA ITS-2 region was amplified from Haemonchus (identified as a H. placei section 3.1) adult worm lysates using a “universal” forward primer complementary to 5.8S rDNA coding sequence (NC1F: 5’-ACG TCT GGT TCA GGG TTG TT- 3’) and reverse primer complimentary to the 28S rDNA coding sequence (NC2R: 5’-TTA GTT TCT TTT CCT CCG CT- 3’) (Stevenson et al., 1995). A 321bp fragment spanning the entire ITS-2 rDNA region was PCR amplified using a 50µl master mix containing final concentrations of 1X thermopol reaction buffer, 2mM MgSO4, 100µM of each dNTPs, 0.1µM

Positions 24, 205 and 219 (indicated in larger font) have fixed interspecies polymorphisms whereas the other listed positions show intra-specific variation. rDNA ITS-2 sequence polymorphisms identified from a total of 66 individual derived from four *H. placei* populations: H1C, H2C, H3C, and H4C.

Figure 1: Sequence chromatogram of 1 out of 66 sequences (named *H. placei* sequences) obtained from 4 populations showing three fixed species-specific positions (P24, P205, P219) of the rDNA ITS-2 sequence of *H. placei*.

forward and reverse primers and 1.25U Taq DNA polymerase (New England Biolabs). Thermo-cycling parameters were 95°C for 5 min followed by 35 cycles of 95°C for 1 min, 57°C for 1 min and 72°C for 1 min with a single final extension cycle of 72°C for 5 min. rDNA ITS-2 amplicons from individual worm lysates were further were sequenced using the reverse primer (NC2R: 5-TTA GTT TCT TTT CCT CCG CT- 3”) on an ABI Prism 377 capillary sequencer. Sequences were edited and aligned with *H. placei* ITS-2 sequences available in Genbank (Acc No X78812) using Geneious Pro 5.4 software (http://www.geneious.com/).

Previous work has identified three single nucleotide polymorphisms (SNPs) in the rDNA ITS-2 (positions 24, 205 and 219) that show fixed sequence specific differences between *H. placei* and other closely related species *H. contortus* (Stevenson et al., 1995). However this study was based on just two *H. placei* and eight *H. contortus* worms obtained from cattle and sheep respectively. Consequently, Chaudhry et al. (2014) further provided that these inter-species differences were fixed when larger numbers of individuals from geographically diverse populations were examined. In the present study, allele-specific PCR primers were developed based on P24 and P219.
SNPs, which will then be used to identify *Haemonchus* populations for the presence of *H. placei*. For this purpose, allele-specific PCR was then applied to screen all 78 individual worms (from 4 populations) collected from cattle and a total of 66 worms were identified *H. placei*, rest of the 12 worms did not amplified with this assay (Figure 1).

The rDNA ITS-2 sequence was PCR amplified and sequenced from DNA derived from 66 worms in four *Haemonchus* populations (identified *H. placei* in section 3.1). In all cases, *H. placei* sequences contained P24 (G), P205 (A), P219 (G) confirming SNPs (Table 2 and Figure 2) previously identified by Stevenson et al. (1995) and Chaudhry et al. (2014). In addition to confirming the three species-specific fixed SNPs, there were 4 sites that showed intraspecific variation in *H. placei* at position 65, 111, 125 and 148 (Table 2).

Accurate identification of parasite species is crucial not only for diagnosis, treatment and control but epidemiological studies and clinical trials. Although sufficient morphological differences exist among adult and larval GI parasitic nematodes to allow their accurate identification, the availability of similar techniques for nematode eggs remains an obstacle to reliable diagnosis. In some cases the structure and size of the egg can be diagnostic; however, in many instances, similarities among eggs from different species and even distinct genera require alternative methods for their differentiation. Presently, the method commonly utilized for GI parasitic nematodes involves in-vitro cultivation of egg to infective third stage larval (L3) recovery and direct collection of adult parasite from slaughtered animals followed by morphological identification. These procedures are labour intensive, time consuming and prone to errors due to variation in egg viability and parasite development in culture. The advent of DNA technology has provided alternative approaches for the identification of parasites and molecular techniques like allele-specific PCR have proven to be useful in species identification. Studies have shown that the rDNA ITS-2 contain reliable genetic markers to distinguish closely-related species of trichostrongyloid nematodes (Gasser et al., 1993; Campbell et al., 1995; Chilton et al., 1995; Stevenson et al., 1995; Wimmer et al., 2004).

*Haemonchus* spp. are important, highly pathogenic blood feeding parasites of cattle in many parts of the world, particular in warmer regions with high humidity, such as Asia, south America and the south-
ne USA. *H. placei* is the most common species traditionally reported from cattle (Gasbarre et al., 2009a; Gasbarre et al., 2009b). Of the four populations examined (one from Sargodha, one from Lahore, one from Okara and one from Sahiwal), the prevalence of 85% *H. placei* suggesting this is still the predominant *Haemonchus* species infecting cattle in Pakistan.

Indeed, inter-species variation in the ITS-2 sequences between *H. placei* and *H. contortus* in cattle, sheep and goats host revealed minor differences such as substitutions of three residues at position P24, P205 and P219, many investigators also indicate the intra-specific variation of ITS-2 sequences among *H. contortus* from domestic ruminant in the world, however very limited information about the genetic variability in *H. placei* in ruminants currently available worldwide and particularly on the south Asian region. This work investigates further insight into genetic relationships of *H. placei* from Pakistani region. Therefore we sequenced ITS-2 region of 66 *H. placei* individuals and our analysis was conducted from four different cattle host to avoid strain specific nucleotide variations. The results demonstrate three species specific SNPs [P24 (G), P205 (A), P219 (G)] and four intra-specific variations sites at position 65,111, 125 and 148 in *H. placei* (Table 2). Of those, position 65, 123 and 148 have been previously shown in *H. placei* (Stevenson et al., 1995; Chaudhry et al., 2014). However position 111 polymorphic site had not been identified previously, so we hypothesized that P111 is a new intra-specific variation present in *H. placei* from Pakistani region. The newly identified genetic variation in the ITS-2 sequence represents a significant addition to databases.

To our knowledge, this is the first study in Pakistan exploring the genetic variation in *H. placei*. These results can further use to monitor *Haemonchus* infection in a context of gastro-intestinal control approaches further integrated to a sustainable agriculture. In order to confirm the development of *H. placei* resistant to anthelmintic in cattle further study must be carried out.
